Wind direction and speed are critical features in Kuwait because they are associated with dust and sand storms, which occur mainly during summer. Wind speed and direction data of June, July and August for the period 1957-85 were collected from the Meteorological station at Kuwait International Airport.

The wind direction data were grouped in four main sectors, i.e., NE, SE, SW and NW. The data were used to calculate the frequency of wind direction and speed, and to construct wind roses for different periods of the 29 years.

The wind analysis showed that NW winds were predominant. NW winds had the highest frequency of occurrence for the period of 1962-1985, and NNW winds had the highest frequency during the period of 1957-1961. The analysis also showed that moderate wind speeds (8-18 mile/hour) had the highest frequency during the period 1957-1985 especially with the NW direction, however, the result does not show any major trend in the wind direction and speed.

ABSTRACT (SUMMARY OF NOT MORE THAN 300 WORDS)			المستخلص (ملخص لا يزيد عن ٣٠٠ كلمة)	

تعتبر سرعة الرياح واتجاهاتها من العناصر المناخية التي تتسبب في نشاط العوامل الترابية وتساقط ذرات الغبار وخاصة في فصل الصيف في دولة الكويت ، ونظراً لأهميتها فقد جمعت المعلومات عن سرعة الرياح واتجاهاتها المسجلة في مطار الكويت الدولي خلال شهر يونيو ويوليو وأغسطس للفترة ما بين ١٩٥٧ - ١٩٨٥ ميلادي .

المعلومات التي جمعت تعتمد على معدل سرعة واتجاه الرياح في خلال الساعة مقاسة على ارتفاع ١٠ متر من سطح الأرض .

كما تم حصر اتجاه الرياح في أربع مجموعات رئيسية وهي كالتالي:-
شمال شرقي ، جنوب شرقي ، جنوب غربي ، شمال غربي

ولقد دلت نتائج الدراسة على أن مجموعة الرياح الشمالية الغربية هي السائدة على المجموعات الأخرى وخاصة أن اتجاه الشمال الغربي هو السائد على الاتجاهات الأخرى في المجموعة نفسها . ولقد أثبتت الدراسة أيضاً أن اتجاه الرياح من الشمال الغربي كان مسيطرًا خلال الفترة ما بين ١٩٦٢ - ١٩٨٥ - ١٩٥٧ ، أما الاتجاه من الشمال شمالي غربي كان المسيطر في الفترة ما بين ١٩٦١ - ١٩٧١ . أما بالنسبة لسرعة الرياح فلقد أثبتت الدراسة أن السرعة المحددة ما بين ١٨-٨ ميل في الساعة هي السائدة في خلال الأعوام التي أجريت عليها الدراسة .

Introduction

This study deals with wind speed and direction not just as natural phenomena, but also in terms of their influence on the human environment, i.e., structures and landscape. Therefore, this report is addressed to those who are interested in exploring the role of the wind in design and in finding innovative ways to improve the quality of life.

Wind speed and direction are critical features in Kuwait because they are associated with dust storms and mobile sand phenomena. Summer winds cause environmental problems such as fine surface sediments and sand sheets in the desert, as well as severely polluting the air and reducing visibility, which affects air navigation.

The analysis of wind data would be very useful to determine trends in wind speed and direction and to predict sand and dust storms in Kuwait, and to plan environmental protection accordingly.

As the frequency of dust occurrence is highest in summer (Safar, 1980), wind data analysis at the peak of this season is of critical importance for the study of dust storms and mobile sand phenomena.

The study of climatic trends requires long records of representative climatological data. The Kuwait International Airport (KIA) weather station has daily meteorological data from 1957 and, for the purpose of creating the 1957-1985 averages, these data were entered in KISR's Computer.

The aim of this study is to describe the trends in wind direction and speed in Kuwait during the dusty season (June, July and August) in the 29 year period 1957 - 1985.

Wind Measurements

The instrument used at Kuwait International Airport to measure wind direction and speed is the electrical anemograph. A wind vane is mount-

ed on a tower at a height of 10 m above ground level. The continuous fluctuations of wind direction and speed can be visualized, at time intervals of one hour or less, from the traces recorded on the anemograph's chart. Fig. 1 shows a typical daily anemograph chart.

To obtain hourly averages of wind directions or speeds a simple interpolation can be performed on the anemograph chart. The wind direction fluctuations are recorded on a time scale at the top of the chart. The wind speeds are recorded on the bottom of the chart.

The wind directions are observed in degrees on a compass scale which refers to the direction from which the wind is blowing. The wind speed is measured in different units such as knot, miles per hour (mph), etc. The wind speed data used in this study were recorded in miles per hour.

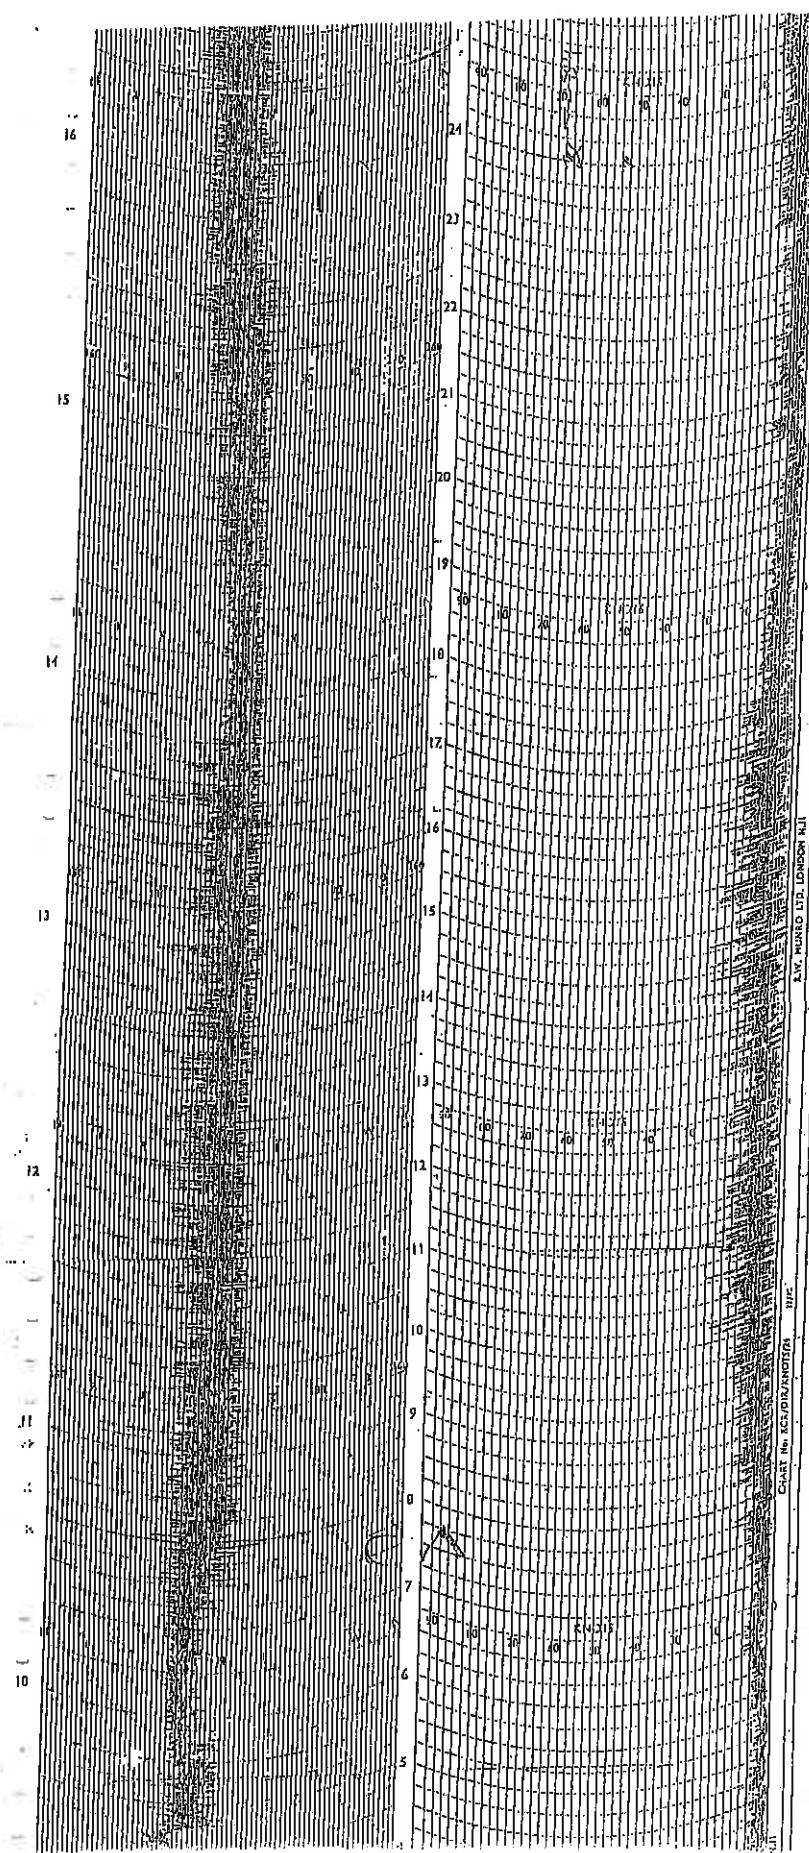

Data Collection

Investigations were made on the availability and reliability of surface wind data. In Kuwait, only the meteorological station at Kuwait International Airport (KIA) was set to record daily meteorological data, including surface wind data. The KIA also had the longest continuous period of records. It was decided that for the purpose of this study only the surface wind data from KIA would be used.

Two types of surface wind data records were available from KIA. The first is the average of the last ten minutes of each hour, which was used for aviation purposes; the second is the hourly average, which was used for climatological records.

In view of this, a computer test run was made for the records of four years (1978-1981) to compare the ten-minute averages with the averages for whole hours. The results are shown in tables 1 and 2, respectively.

Significant differences were observed between the two sets of averages. For example, the total frequency percentage of N winds was 2.5 for the last-ten-minute averages and 9.2 for the hourly averages; for NW

winds the figures were 8.3 and 20.8; and for NWW winds they were 6.0 and 20.6, respectively. These discrepancies are attributed to the fact that wind speed and direction vary widely within one hour, which means that the average for the last ten minutes (i.e., only about 17% of the total time) is not representative. It was therefore decided to use only the hourly averages for this study.

The data available at KIA for the period 1957-1985 were collected. The wind direction data are recorded on anemograph charts, and to obtain hourly averages the wind directions were interpolated to degrees.

Wind direction data were grouped into 16 sectors (Table 3). Three additional categories were added for "calm" readings (no wind), "variable" readings (wide fluctuations within the hour) and missing data.

Wind speed data were grouped on the basis of Beaufort wind scale (Table 4). For the purpose of this study the scale was reduced to five categories (Table 5).

Finally, the data were stored in KISR's computer on a monthly and annual basis.

Table 3. Wind Direction and the Coded Degrees

Moderate	8 - 18
Strong	19 - 31
Gale	≥ 32

Data Analysis

The frequency percentages of wind direction and wind speed were calculated for each of the three months (June, July and August) for 29 years.

Wind Direction

The frequency percentages of winds from each of the 16 sectors defined in Table 3 were calculated for each year. The results are shown in Tables A1, A2 and A3 in Appendix A. These tables, as well as Table 6, show that four directions, i.e., N, NNW, NW and WNW, were among the prevailing wind directions in most of the 29 years.

On the basis of these observations, the decision was made to consider these four wind directions as one sector.

Therefore, for the purpose of this study, it was decided to group the sixteen wind directions into four main sectors clockwise as follows.

1. Northeast sector, consisting of the following:

- * North Northeast (NNE)
- * Northeast (NE)
- * East Northeast (ENE)
- * East (E)

2. Southeast sector, consisting of the following:

- * East Southeast (ESE)
- * Southeast (SE)
- * South Southeast (SSE)
- * South (S)

3. Southwest sector, consisting of the following:

- * South Southwest (SSW)
- * Southwest (SW)
- * West Southwest (WSW)
- * West (W)

4. Northwest sector, consisting of the following:

- * North (N)
- * North Northwest (NNW)

- * North West (NW)
- * West Northwest (WNW)

Monthly Wind Direction Frequency. Figures 2a, 2b and 2c present the frequency distribution of the four wind direction sectors in June, July and August, respectively. The figures show that, with only one exception the Northwest sector has the highest frequency in each of the three months for the last 29 years.

A comparison of the three figures shows that the frequency of the Northwest wind has some stability during the month of June (Fig. 2a), and less stability during July and August (Figs. 2b and 2c). The August frequencies were particularly unstable from 1957 to 1968: both the highest and the lowest values in the 29 years were recorded during this period.

The other three sectors showed some stability during the months of June and July with some exceptional years such as 1962, 1976 and 1979.

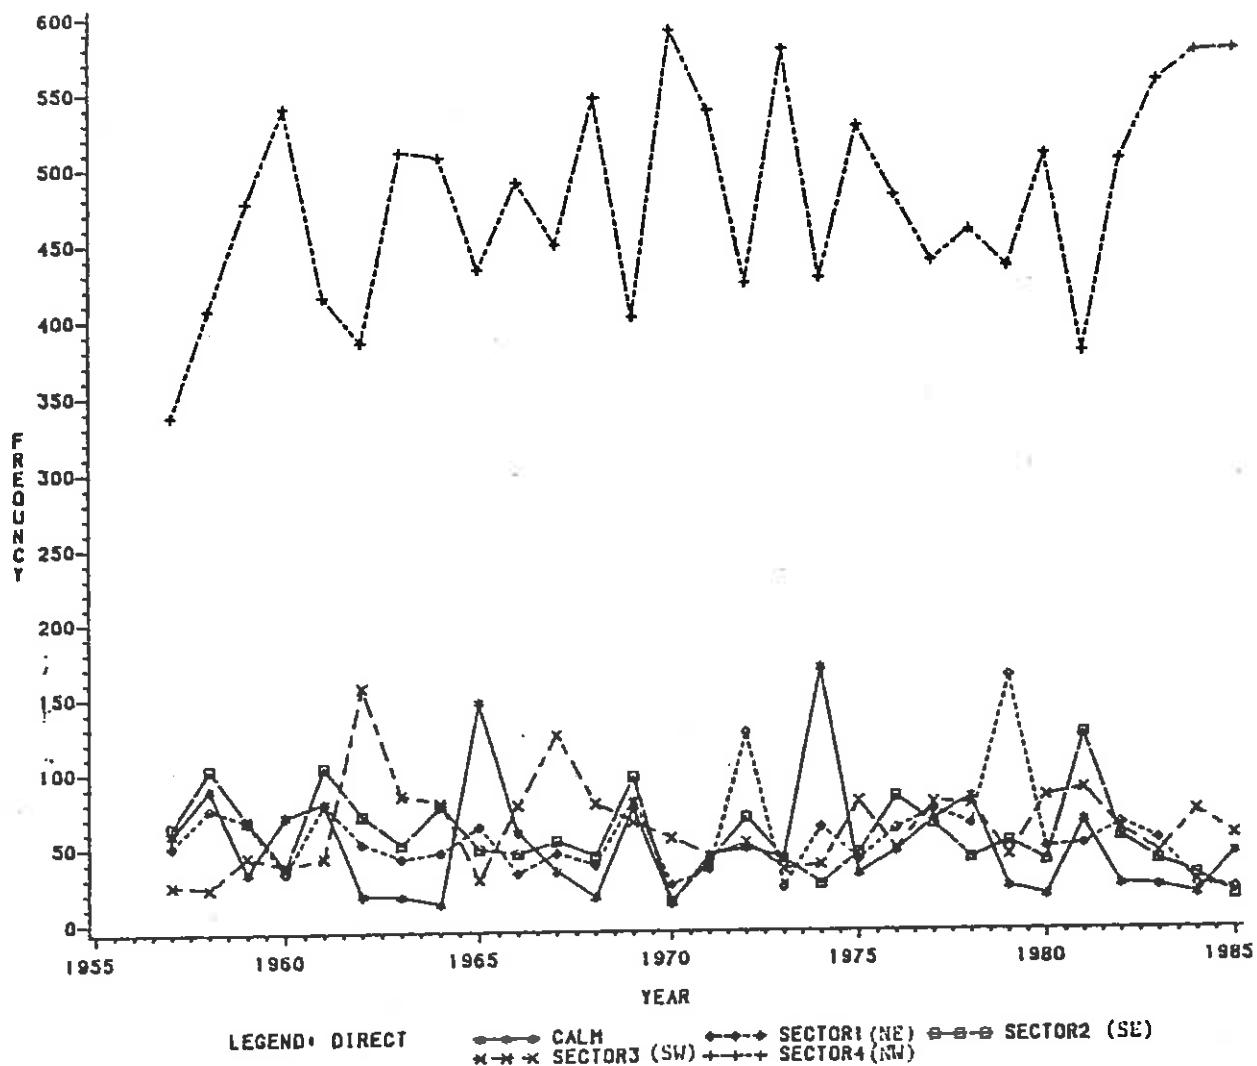

The Southeast and Southwest sectors had the highest frequencies during the month of August 1962 and 1967, respectively (Fig. 2c). During this month, the frequencies of these sectors were unstable and varied from year to year, especially during the early years (1957 to 1968).

Calms were less frequent in June (Fig. 2a) and more frequent in August (Fig. 2c). This category was not included in the analyses of the study because it does not contribute to dust storms and sand mobility.

Overall Wind Direction Frequency for the Three-Month Period. Figures 3a to 3d present the frequency of wind from the four sectors during the whole three-month period. Fig. 3a shows that the frequency of the Northwest sector was lowest in August 1962 and 1985, and highest in July 1959, 1971 and 1983. It also shows that August had the highest fluctuations and June had the lowest.

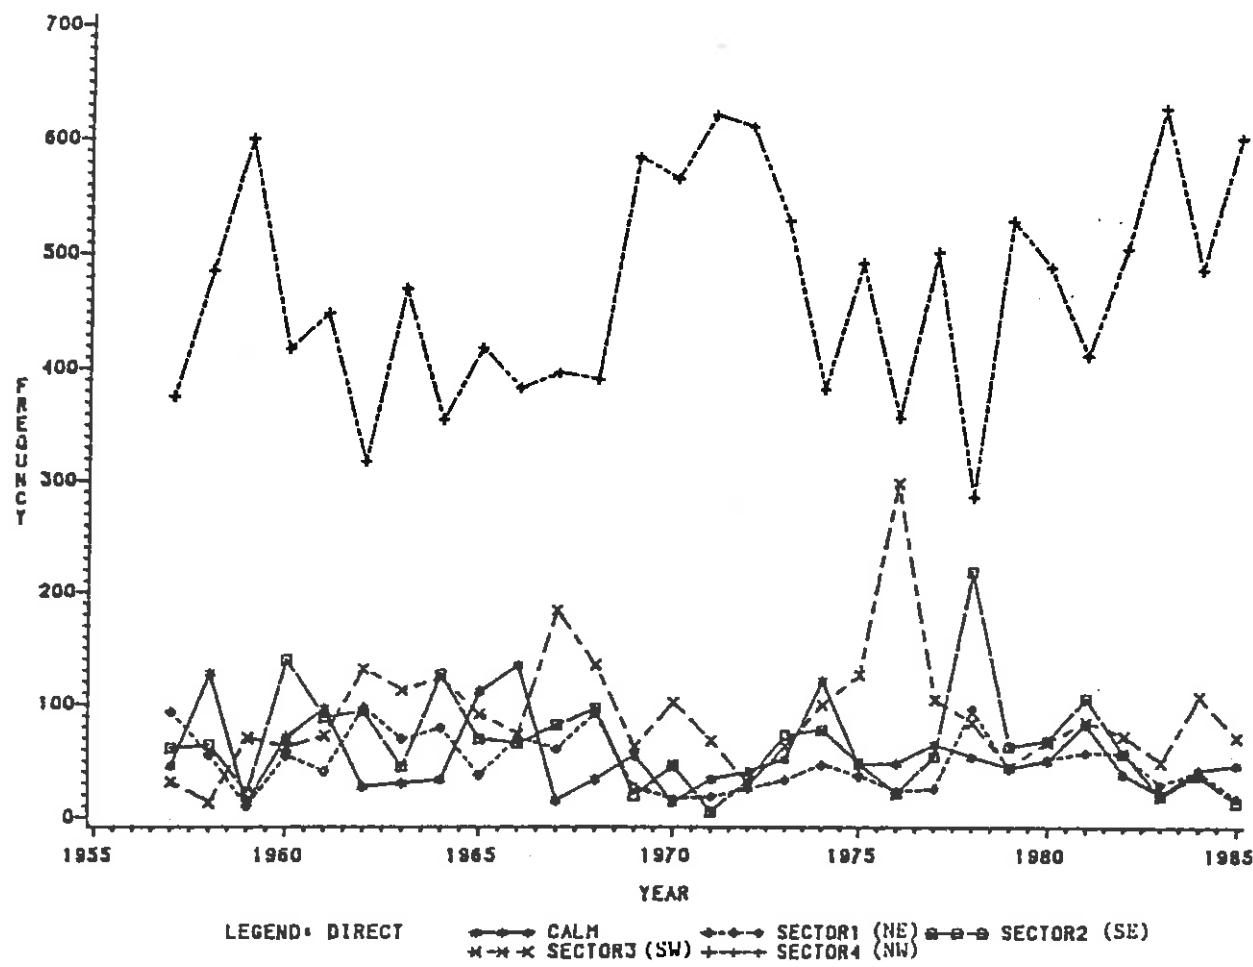

Winds from the Southwest sector were more frequent in August, except in 1962, 1977, and 1981 when higher frequencies were observed in June and July (Fig. 3b).

Similar results were obtained for the Northeast and Southeast sectors. The frequency of Northeast winds varied from one month to another

with some extreme years such as 1962, 1972, 1979 and 1985 (Fig. 3c). The frequency of Southeast winds was higher in August, when it also showed an apparent peak cycle approximately every three or four years.

In order to test the changes in the monthly frequency means of the three month for the four wind direction sectors, Table 7 was used to test whether there were significant differences among the wind means during the three months. The results of this table showed that the frequency means of Southwest sector during the three months were significantly different at 0.05 level, and F-ratio was 5.20 (P 0.05).

The table also shows that the Northwest sector has the highest monthly hourly mean frequency, and the lowest variation coefficient during June, $\bar{X} = 477.7$ and C.V = 0.14 respectively. The Northeast sector has the lowest monthly hourly mean frequency and higher variation coefficient during July, $\bar{X} = 47.9$ and C.V = 0.53. The coefficient variation was used to compare variation between wind sectors and to measure the relative consistency of average frequency occurrence.

Wind Direction Frequency within Each Sector.

The Northwest Sector. Wind direction frequencies within the Northwest sector during the months of June, July and August are presented in Figs. 4a to 4c.

In June, the NW wind was the prevailing wind in this sector (Fig. 4a). It had a fairly smooth linear frequency trend during the first period from 1957 to 1968, increasing gradually to a maximum in 1968. This trend was rapidly reversed in the following four years (1969 to 1972).

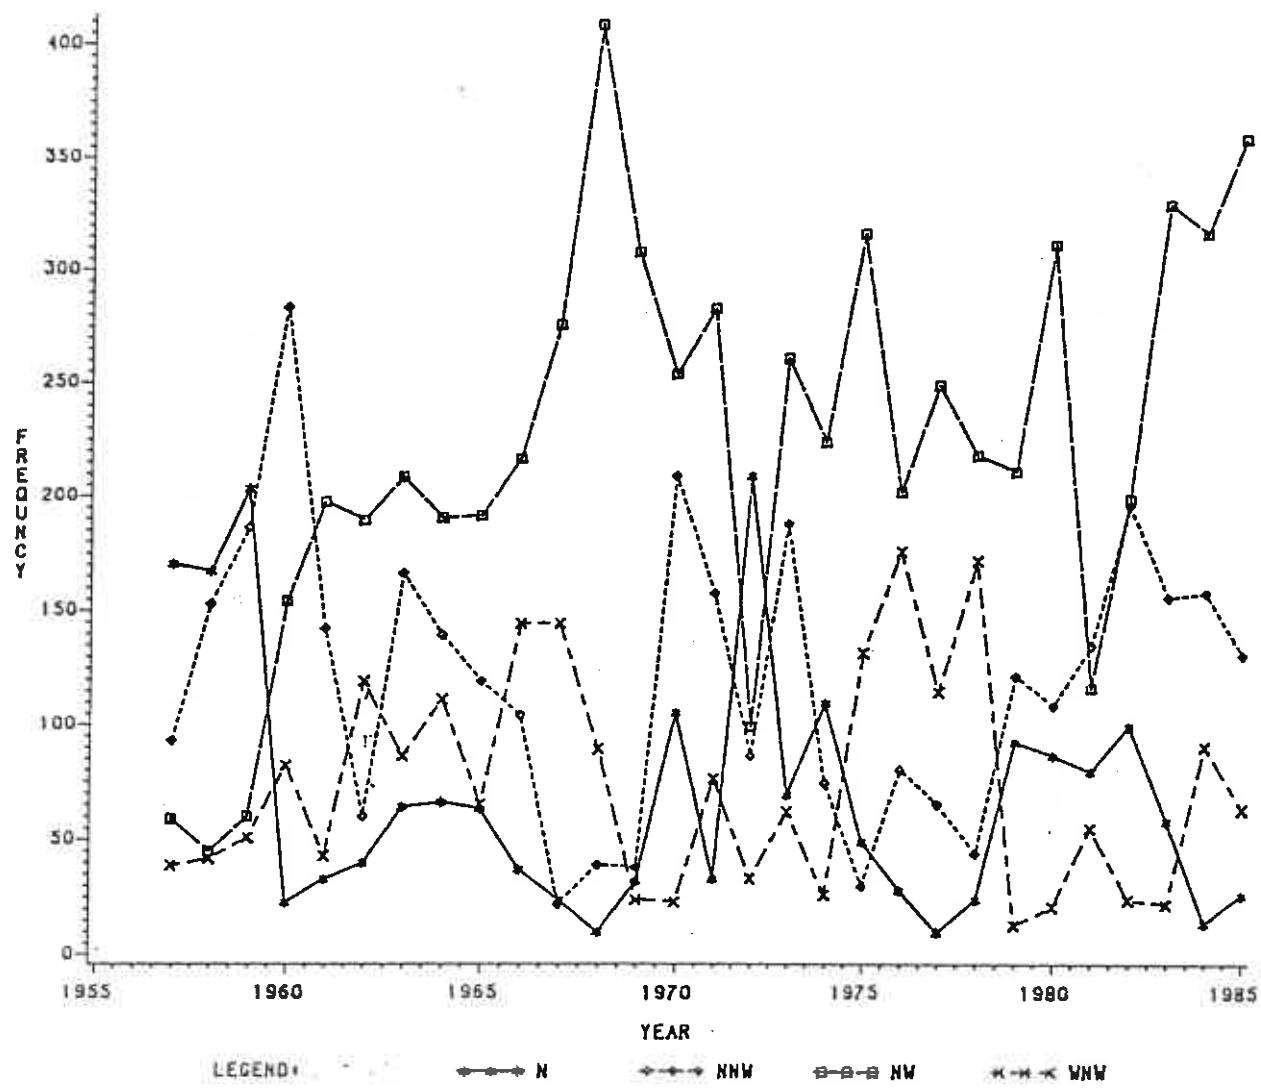

This trend was rapidly reversed in the following four years (1969 to 1972). The correlation coefficient (r) between the frequency monthly means and the period between 1957 to 1968 in June was found to be significant at 0.05 level, and $r = 0.65$. When the t-test was used to test the significance of this correlation between these two observation, it was found that the t-value was 4.44, and the correlation coefficient was significant. The t-value is calculated by the formula

$$t = r \frac{\sqrt{N-2}}{\sqrt{1-r^2}}$$

Table 7. Summary of the Wind Direction Sectors of the Three Months (1957-1985)

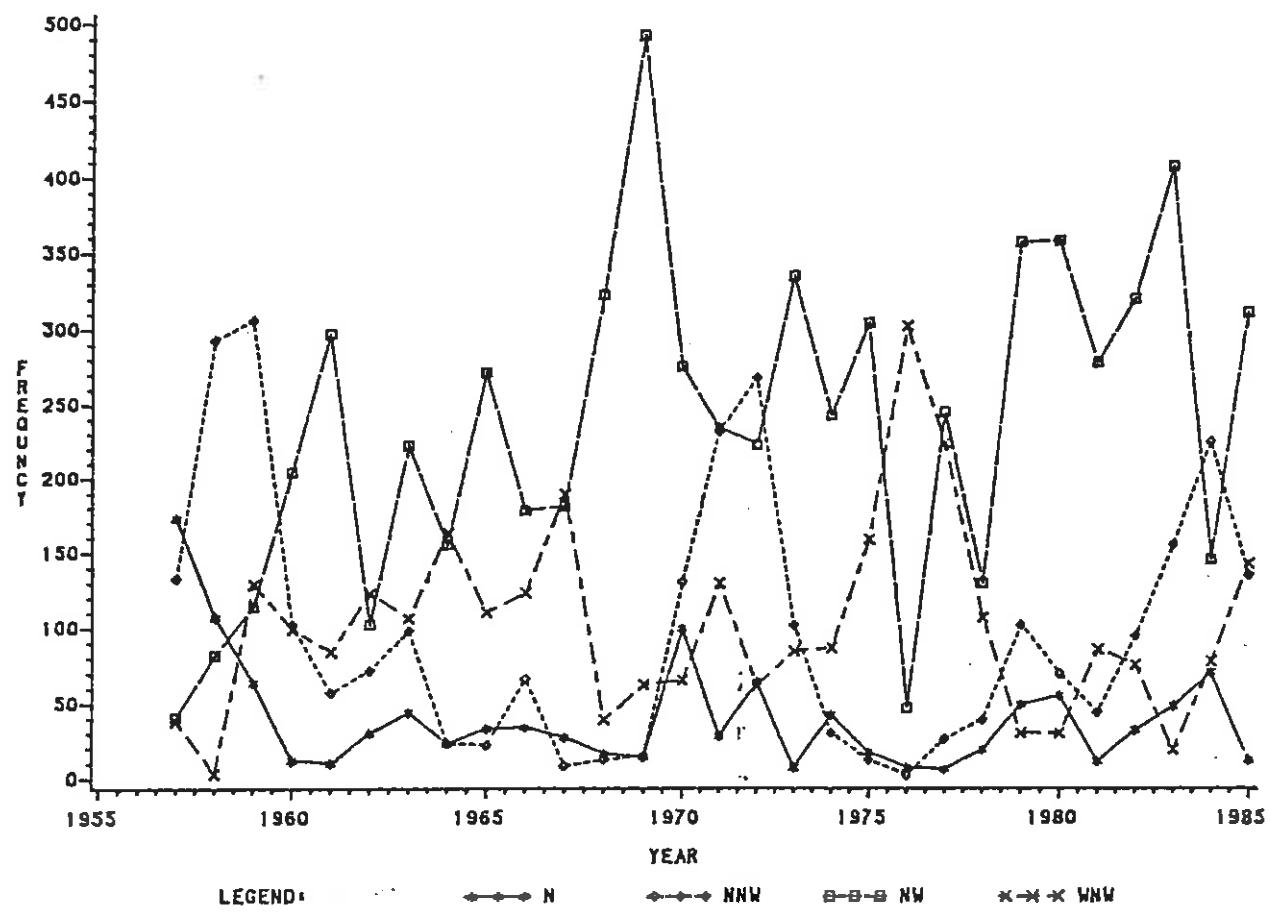

Sector	Month	\bar{X} (h)	SD	CV	Min. Frequency (h)	Max. Frequency (h)	F

Fig. 4b. Frequency distribution of wind directions in the northwest sector during July (1957 - 1985).

KISRX 20762

Fig. 4c. Frequency distribution of wind directions in the northwest sector during August (1957 - 1985).

where:

r = correlation coefficient

N = Number of observations

Figure 4a also shows that during the period of 1957 to 1959, the N and the NNW winds were prevailing. The frequency percentage of the N wind ranged between 21.8% in 1957 and 26.1% in 1959 (Table A1, Appendix A). In 1972, the N wind had the highest percentage of occurrence $C = 10.3\%$.

Figure 4b and 4c present the NW sector of July and August. The figures show that the NW winds frequency increased from 1957 to 1961, and again from 1966 to 1969.

The highest frequency of the NW wind occurred in July 1969 when $R = 66\%$ and $C = 7.2\%$ (Table A2, Appendix A), and the lowest in July 1957 ($R = 5.5\%$ and $C = 0.6\%$). For the month of August, the highest frequency was in 1968 ($R = 6.14\%$ and $C = 8.1\%$) and the lowest in 1962 ($R = 6.2\%$ and $C = 0.8\%$).

When the relationships between the NW wind and the other winds in NW sectors was studied, it was found that most of the correlation coefficient were negative or very low (Table 8). For example, in June the correlation coefficient was -0.70 between N and NW, -0.35 between N and W, and 0.48 between N and E. The NW wind had negative correlation coefficients with most wind directions during August. These negative correlation coefficients indicates that an opposite relationship exists between these wind directions. The purpose of the correlation coefficient is to express in statistical terms the degree of relationship between two variables. If the relationship is perfectly positive, r will be 1.00. If the relationship is perfectly negative, it will be -1.00. If there is no relationship, r will be zero. If the two observations are related, the coefficient will have a value between zero and -1.00 for a negative relationship, and between zero and 1.00 for a positive relationship (Hays, 1981).

The correlation coefficient between N and NNE were 0.48, 0.65, and 0.69 for June, July, and August respectively, and between the WNW and WSW, the correlation was 0.81 in July. These positive coefficients

Note: Coefficients below #0.12 were not included (no correlation)

indicate that the N wind relates highly with NNE during the three months, and the WNW relates highly with WSW, especially in July.

The Southwest Sector. Figures 5a to 5c present the frequency distribution of the wind directions of the Southwest sector for the months of June, July, and August, and the correlation among the wind directions is shown in Table 9. The figures show that the West wind was prevailing in this sector, and that the SW wind had the highest frequency during 1968 and 1969.

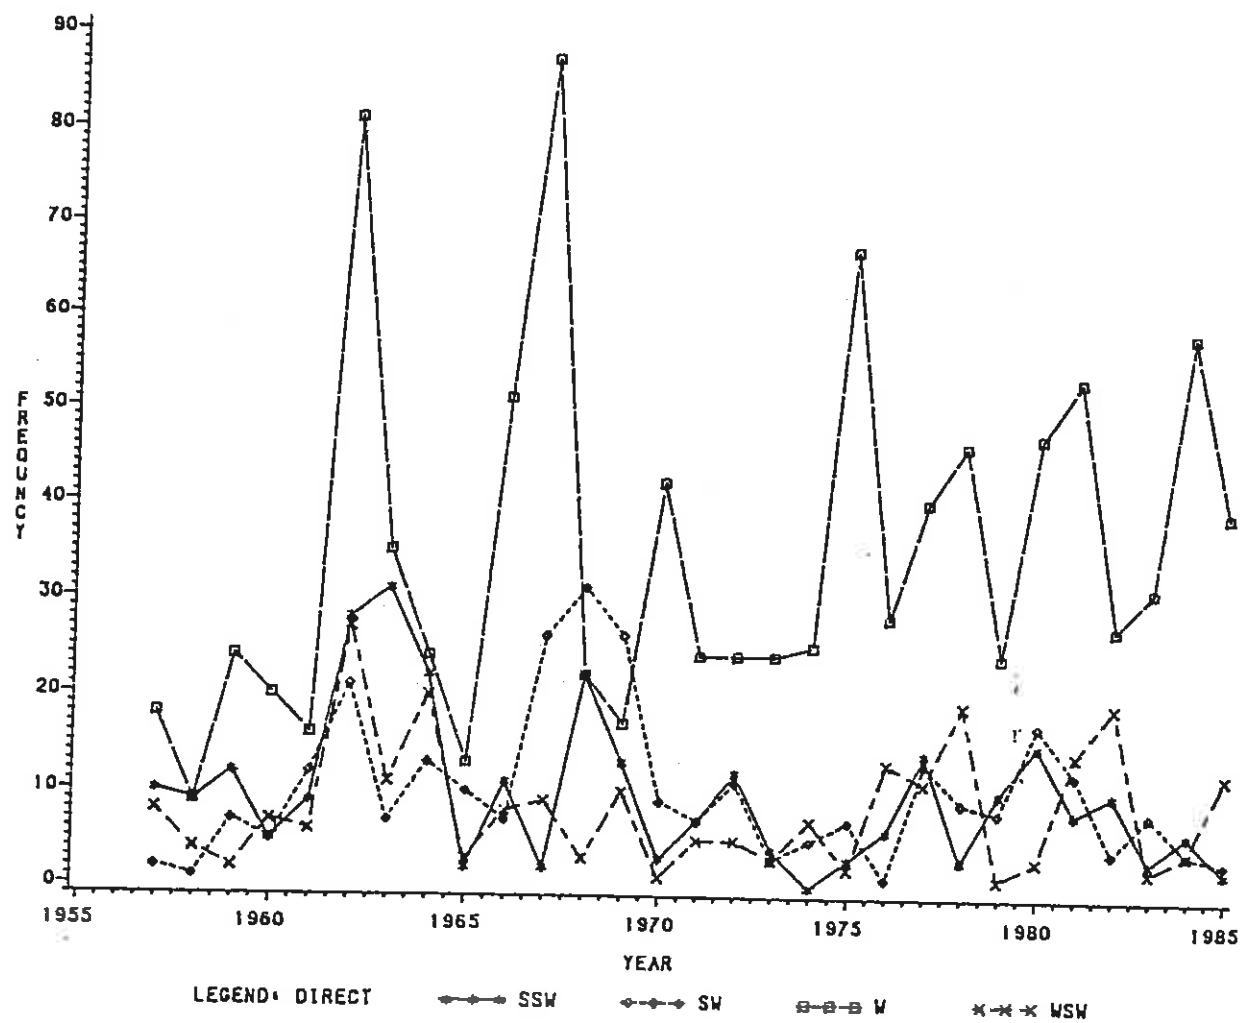

Figure 5a shows that during June the W wind had a lower frequency than in July (Fig. 5b) and August (Fig. 5c), and that its the highest frequency was in June 1967 ($R = 12.1\%$, $C = 8.6\%$, Table A1, Appendix A), July 1976 ($R = 33.5\%$, $C = 14.7$, Table A2, Appendix A), and August 1967 ($R = 32.7\%$, $C = 13.5\%$, Table A3, Appendix A).

Table 9 shows that the correlation coefficients between SSW and SW were 0.40, 0.68, and 0.39 for the month of June, July, and August respectively, and that the correlation coefficient between SSW and NE increased during July to 0.60.

The Northeast Sector. Figure 6a shows no dominant wind, because there are two wind directions, E and NE, that alternate every two to three years. Fig. 6a also shows that the NNE wind had the highest frequency in June 1972 ($R = 8.2\%$ and $C = 15.4\%$, Table A1, Appendix A), whereas E had the highest frequency in July 1962 (Fig. 6b, $R = 7.7\%$ and $C = 8.9\%$, Table A2), and NE had the highest frequency in July 1968 ($R = 7.0\%$ and 20.2% , Table A2). Fig. 6c shows that the E wind is the dominant wind during August.

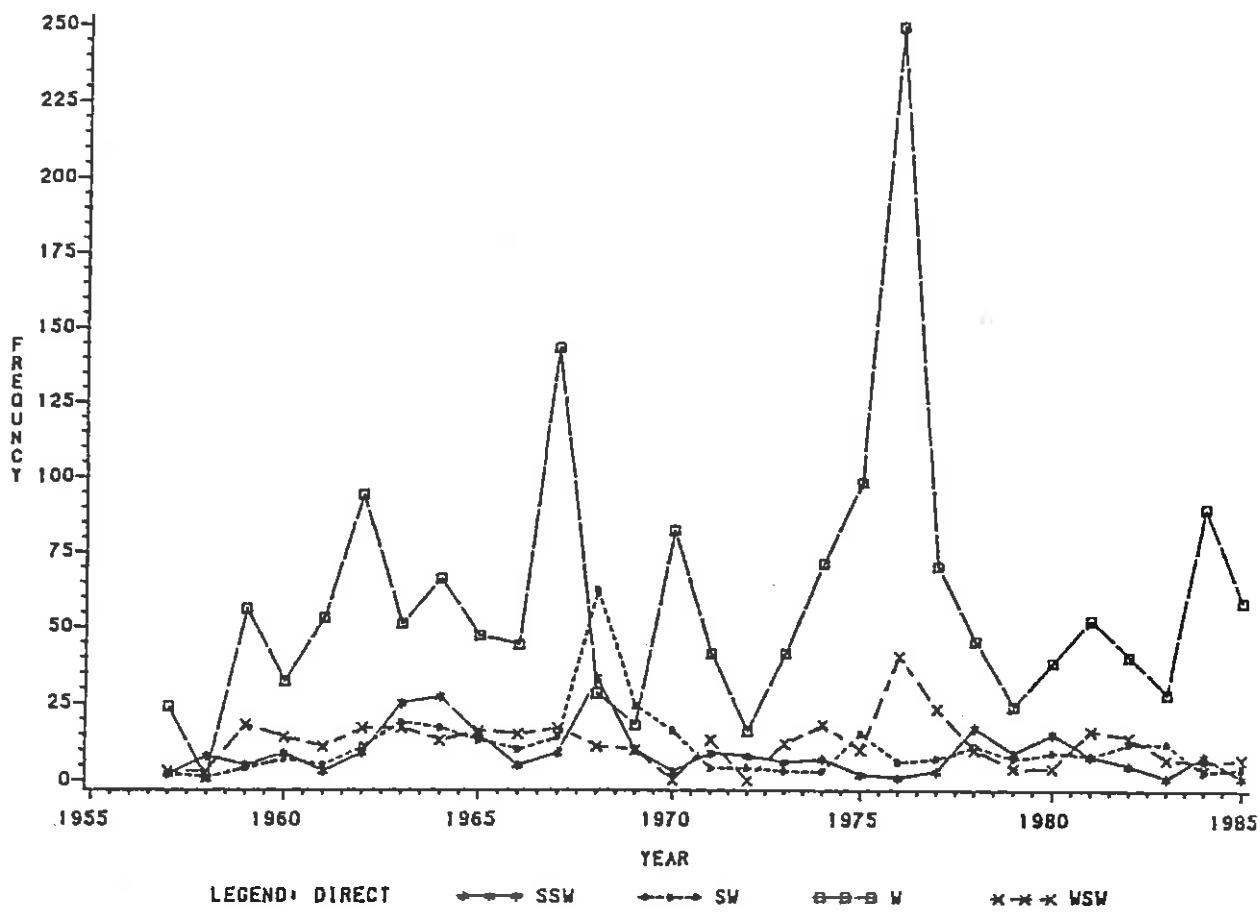

Table 10 shows that there are some positive correlation between NNE and NE (0.49), between NNE and E (0.47), and between NNE and ESE (0.60) during June. The table also showed that the highest positive correlation was 0.91 in August between E and S.

The Southeast Sector. Figs. 7a to 7c present the wind direction within this sector during the three months. The figures show that the S wind was prevailing in June (Fig. 7a) and August (Fig. 7c). The ESE wind's frequency was higher in July (Fig. 7b). Table 11 shows the correlation between the Southeast wind directions. The correlation coeffi-

Note: Coefficients below #0.12 were not included (no correlation)

cient was 0.61 between ESE and SE and 0.66 between SE and SSE in June. In July the coefficients between ESE and SE increased to 0.76. These coefficients indicate that the wind directions in this sector are more highly related than in other sectors, and the variations between their monthly frequency means are less pronounced.

Finally, in order to summarize the monthly frequency means for each wind direction during the three months. Table 12 was used to test whether there were significant differences among monthly frequency means. The table showed that the N, W, and SSW winds have the highest fluctuation. The F-values were 4.19, 3.78, and 4.09, and were significant at 0.05 probability level.

Wind Speed

The monthly frequencies of the five wind speed categories (as defined in Table 5) are presented in Tables 13a to 13c. Table 13a shows monthly frequency of wind speed categories for June. It shows that the most frequent category in June was the moderate category (8-18 mph), and the least frequent was moderate gale (≥ 32 mph). It also shows that the highest mean wind speed was in 1970 ($\bar{X} = 18.40$ mph and SD = 7.43), and the lowest in 1965 ($\bar{X} = 5.74$ mph and SD = 4.6).

On the other hand, the calm category was the highest frequency in 1965 and the lowest in 1970, but this category was not included in the analysis since calm by definition means no wind speed or direction thus the dust mobility tends to rigidity. The daily average wind speeds for these two years are presented in Figs. 8a to 8b, which show that more variation occurred in 1965 than in 1970. The coefficient of variation for 1965, ranged between 75% in August and 82% in July, and in 1970 it ranged between 41% in June and 56% in August.

Tables 13b and 13c show the similar results for July and August. The moderate category had the highest frequency and the gale category had the lowest.

Figs. 9a to 9c show that the frequency of the moderate wind speed category (8-18 mph) tended to decrease approximately every four to five years (1957, 1961, 1965, 1969, 1974, 1978 and 1981).

Wind Direction and Wind Speed

It can be concluded from the previous sections on wind direction and wind speed that there was no clear linear trend in the behavior of wind. However, the most frequent feature during June, July and August is NW and NNW winds with moderate wind speeds.

In June, the wind direction changed to N and NNW and the monthly mean wind speed increased to 15 mph; in July NW became the prevailing direction and the wind speed ranged between 8 to 15 mph; and in August the wind direction usually turned to NW and WNW with a decrease in wind speed (7 to 13 mph).

It can also be concluded that the NNW and NW winds were prevailing during the last 29 years, with some variations such as the S wind prevailing during 1962 and 1969, and the E during 1962 and 1965.

To study the effect of wind speed on wind direction for the last 29 years, wind roses were constructed for every five-year periods, such as 1957-1961, 1962-1966, 1967-1971, 1972-1976, 1977-1981, and for one four-year period, 1982-1985. The five-year interval was selected because of the similarity of wind directions and wind speeds. For example, the interval of 1957 to 1961 has similar yearly wind speed means and the prevailing directions were N and WNW. The interval of 1962 to 1966 has a greater monthly wind speed mean frequency and the prevailing wind directions were NW and WNW. Similar finding were used to group the years (Table 14).

A wind rose is a polar plot of the frequency of wind flow as a function of direction (Graedel, 1977).

For example, Tables 15 to 20 show the frequency percentage of wind speed and direction for each five year period. Figs. 10a to 15c show the wind roses of the data for the same period. The tables show that during the three months, the highest frequency of wind speed was within the moderate range (8-18 mph) except for 1965, and the gale category (wind speed ≥ 32 mph) had the lowest frequency. The tables also show that the light wind speed category (1-7 mph) had the second highest frequency percentage in August except for the first five years (1957-1961), when it had the highest frequency. During June and July the light and

1st = First prevailing wind direction

2nd = Second prevailing wind direction

\bar{X} = Mean wind speed

SD = Standard deviation

strong wind categories had variable frequencies, but for the period 1967-1976 strong wind speeds (19-31 mph) were more frequent than light wind speeds.

Tables 21-26 present the frequency percentage of wind speed and wind direction for each month in each five-year period. The tables show that the Northwest sector (sector 4) is the dominant direction, especially for moderate wind speeds.

Figs. 16a, 16b and 16c present the overall 1957-1985 wind roses for June, July and August, respectively. These figures show that NW was the dominant wind direction for the 29 years.

Summary and Conclusion

In this study we have presented some preliminary data analyses, and some diagnostic tools for wind direction and speed. These analyses were used to describe the trends during the dust storm season, i.e., June, July and August, for 1957-1985.

There was undoubtedly much information available which the study does not exploit. In particular, the valuable information that contained in the records of wind direction, and adequately into a model was another major challenge. This is because little work appears to have been done on time series of angular observations. Therefore, most of the preliminary analysis of this study were presented on the previous sections and could be summarized as follows:

The Northwest and North Northwest winds were the prevailing winds, but there was no linear trend in the behavior of either wind direction or wind speed from 1957 to 1985. There were, however, some indications that the NW wind followed smooth trends during June from 1957 to 1968, when the correlation coefficient between the monthly mean frequency and years was 0.65. The highest mean frequency of NW winds was in June ($\bar{X} = 477.7$), with a relative variation of -0.14, and the lowest mean frequency was in August with $\bar{X} = 416.9$, and $CV = 0.28$.

The mean frequency of SE winds appeared to have a peak cycle approximately every three to four years during August, with the highest

mean frequency and coefficient of variation in August ($\bar{X} = 81.4$ and $C.V=0.60$), and the lowest in June ($\bar{X}=56.2$ and $C.V=0.26$).

Most correlation coefficients between NW and NNW and other wind directions were low or negative, especially in June and August.

During June, July and August the N, W, and SSW winds had the highest fluctuation with coefficients of variation of 92.2%, 80% and 87% respectively.

Wind speed was seen to vary with both daily and monthly, but these effects are neither strong nor stable. However, in the long term these effects do have important implications on the dust storms and mobility of sand.

The monthly frequency means and variation of wind speed were shown to peak approximately every four to five years. It seems that the variability is small but there are definite peaks between 1957 and 1961, between 1962 and 1967, and so on.

Wind speed reached its lowest in August of every year. The daily mean frequencies were very similar in most years, but 1965 and 1970 were exceptional years.

The wind roses charts showed that NW and NNW winds had the highest frequency. These wind directions were mainly associated with moderate wind speeds (8-18 mph), and the frequency of light wind speed (1-7 mph) increased in August except for the period from 1957 to 1965.

On the basis of the finding and conclusions of this study, the following suggestions are made.

1. A comparison study should be conducted between more than two weather stations to study the changes of the wind speed and direction at different areas.
2. A study of the effect of south and west winds on the movement of dust storms should be undertaken. These two winds have shown to behave differently behavior than other winds through the period of this study.

Note:

R = The percentage frequency of a wind direction during each year.

C = Percentage duration of wind direction in that year to total duration in the same direction during 29 years.
